Linear Regression Model (A Family of models, H)

- Independent variable expressed as a linear combination of dependent variables
- $y = w_0 + w_1 x_1 + \dots + w_k x_k$
- let $x_0 = 1$ and rewrite the above formula
- $y = w_0 x_0 + w_1 x_1 + \dots + w_k x_k$
- that is $\mathbf{y} = \mathbf{w}^T \mathbf{x}$
- different $\mathbf{w} \implies \text{different model(h)}$ in the family(H)

How to determine good model or bad model?

- Commonly, want a model(h) that minimizes MSE of insample predictions
- $MSE = \frac{1}{n-k-1} \sum (y^{(i)} y^{(i)})^2$
- where $y^{(i)} = \mathbf{w}^T x^{(i)}$
- So the problem, stated in optimization term is:

 $\min_{\mathbf{w}} MSE = \frac{1}{n-k-1} \Sigma (y^{(i)} - \mathbf{w}^T x^{(i)})^2 s.t. nothing \qquad really...$

Sounds complicated....But

• in R, it is as simple as

- and we got the h now.
- We will talk about how this is solved in futhure.

So... agin how good is the model?

- For now, let's only judge the model with the data we have in hand
- look for the Adjusted R-squared value

summary(h)
